## Abstract

We consider the numerical integration of high-order linear non-homogeneous differential equations, written as first order homogeneous linear equations, and using exponential methods. Integrators like Magnus expansions or commutator-free methods belong to the class of exponential methods showing high accuracy on stiff or oscillatory problems, but the computation of the exponentials or their action on vectors can be computationally costly. The first order differential equations to be solved presents an algebraic structure (associated to the companion matrix) which allows to build new methods (hybrid methods between Magnus and commutator-free methods). The new methods show similar accuracy as previous exponential methods with a reduced complexity. Additional parameters can be included into the scheme for optimization purposes. We illustrate how these methods can be obtained and present several sixth-order methods which are testes in several numerical experiments.

## 1 Introduction

In this work we consider the numerical integration of the  $N$ th-order non-autonomous and non-homogeneous linear differential equation

$$\mathcal{L}(t)x = g(t), \quad (1)$$

where  $\mathcal{L}(t)$  is a non-autonomous linear operator

$$\mathcal{L}(t)x = x^{(N)} + f_{N-1}(t)x^{(N-1)} + \dots + f_1(t)x' + f_0(t)x \quad (2)$$

and  $x, g \in \mathbb{C}^{m \times d}$ ,  $f_i \in \mathbb{C}^{m \times m}$ ,  $x^{(i)} \equiv \frac{d^i x}{dt^i}$ .

It is usual to write eq. (1) as a first order non-homogeneous linear system of equations. However, to simplify the analysis, we write the non-homogeneous

problem as a<sup>1</sup>  $(N + 1)$ -dimensional homogeneous problem by introducing  $z = (y, 1)^T \in \mathbb{C}^{N+1}$ ,  $y \equiv (y_1, \dots, y_N)^T = (x, \dots, x^{(N-1)})^T$ ,  $G(t) = (0, \dots, 0, g(t))^T \in \mathbb{C}^N$  which satisfies the homogeneous linear equation

$$z' = M(t)z, \quad z(0) = (y(0), 1)^T, \quad (3)$$

with

$$M(t) = \begin{pmatrix} A(t) & G(t) \\ 0_N^T & 0_1 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 & \cdots & & 0 & 0 \\ & 0 & 1 & \ddots & & 0 & 0 \\ \vdots & & \ddots & \ddots & & \vdots & \vdots \\ & & & & 1 & 0 & 0 \\ & & & & 0 & 1 & 0 \\ -f_0 & \cdots & & -f_{N-2} & -f_{N-1} & g \\ 0 & 0 & \cdots & 0 & 0 & 0 & 0 \end{pmatrix} \quad (4)$$

where  $0_N$  is the zero vector of dimension  $N$ , and  $A \in \mathbb{C}^{N \times N}$  is the companion matrix.

The second order autonomous matrix differential equations of Apostol-Kolodner type [4, 17] and its generalization to higher order [16, 25]

$$x^{(N)} = Mx$$

belong to this class. These equations have been extensively studied and the formal solution can be written in a closed form in terms of a series expansion. However, if the matrix  $M$  is time-dependent, a numerical method is required.

On the other hand, high order nonlinear differential equations of the form

$$F(t, x, x', \dots, x^{(N)}) = 0$$

arises in many fields in physics and engineering (see [5, 20, 22, 26] and references therein) either with initial or boundary conditions. The shooting method for the problem with boundary conditions usually requires the numerical integration of a non-autonomous linear equation. The method of quasilinearization also requires the numerical integration of non-autonomous linear equations of the form (1) iteratively [5].

We also remark that the numerical integration of a close to a linear problem

$$\mathcal{L}(t)x = g(t) + \epsilon \mathcal{N}(t, x) \quad (5)$$

where  $|\epsilon| \ll 1$  and  $\mathcal{N}$  is a nonlinear operator depending on  $t, x, \dots, x^{(N-1)}$ , can be efficiently carried out if the linear part is numerically integrated to a relatively high accuracy and separately from the non-linear part. Then, splitting methods for perturbed problems can be used and have shown a high performance [9].

---

<sup>1</sup>For simplicity in the presentation and without loss of generality, we will take  $m = d = 1$  and  $t_0 = 0$ .

In the autonomous situation, the solution of (3) can be written in closed form

$$z(t) = \exp(tM)z(0) \quad (6)$$

or, equivalently,

$$y(t) = e^{tA}y(0) + t\varphi(tA)g = y(0) + t\varphi(tA)(Ay(0) + g), \quad (7)$$

where  $\varphi(z) = (e^z - 1)/z$ . In some cases it can be more convenient, from the numerical point of view, to use approximations to the exponential matrix acting on a vector and in some other cases it is preferable the use of the  $\varphi$  matrix acting on a vector [1, 13, 19, 21, 24].

If the problem is explicitly time-dependent a closed-form solution is not available and numerical methods have to be used on a time mesh (for simplicity, we consider a constant time step:  $t_0 = 0, t_1 = h, \dots, t_N = Nh = t_f$ ). Standard methods like Runge–Kutta, multistep or extrapolation methods are, in general, not suitable for problems where the matrix  $A$  has a relevant algebraic structure (e.g. if  $f_{N-1} = 0$  the system is volume preserving) or if the solution is oscillatory.

Alternatively, one can use exponential methods like Magnus and Fer expansions or commutator-free methods. They preserve the algebraic structure of the exact solution and show a high performance for stiff and oscillatory problems. The main drawback is the computational cost to compute the action of the exponentials on vectors. While the computation of the exponential of a companion matrix acting on a vector can be carried out at a moderate cost for relatively small time steps, the exponents appearing in Magnus and Fer methods are much more involved (and computationally costly) due to their reduced sparsity.

Commutator-free methods correspond, for this problem, to a composition of exponentials of companion matrices and then can be computed efficiently. The main difficulty is that at least two exponentials are necessary to obtain fourth-order methods in the time step,  $h$ , and at least five for sixth-order methods<sup>2</sup>. In addition, for methods of order greater than four, at least one of these companion matrices has to be integrated backwards in time, and this could cause step-size restrictions for stiff problems.

In this work we analyze the structure of the elements associated to the Lie algebra generated by the matrix  $M(t)$  evaluated at a given set of points, say  $M_1 = M(\tau_1), \dots, M_k = M(\tau_k)$  for some values of  $\tau_1, \dots, \tau_k$ . By definition, a linear combination or commutators of elements of a given Lie algebra remain

---

<sup>2</sup>A four-exponential sixth-order method exists, but it shows a very poor performance and it is not recommended in practice.

in the Lie algebra. In addition, we observe that

$$C_\sigma = \sum_{j=1}^k a_j M_j = \begin{pmatrix} 0 & \sigma & 0 & \cdots & & 0 & 0 \\ & 0 & \sigma & \ddots & & 0 & 0 \\ \vdots & & \ddots & \ddots & & \vdots & \vdots \\ & & & & \sigma & 0 & 0 \\ & & & & 0 & \sigma & 0 \\ -\tilde{f}_0 & \cdots & & -\tilde{f}_{N-2} & -\tilde{f}_{N-1} & \tilde{g} \\ 0 & 0 & \cdots & 0 & 0 & 0 & 0 \end{pmatrix} \quad (8)$$

where

$$\sigma = \sum_{j=1}^k a_j, \quad \tilde{f}_i = \sum_{j=1}^k a_j f_i(\tau_j), \quad \tilde{g} = \sum_{j=1}^k a_j g(\tau_j)$$

which we refer as a companion matrix when  $\sigma \neq 0$ . Notice that, when  $\sigma = 0$  the computation the  $\exp(C_\sigma)$  is trivial.

The following properties for the exponential of matrices or their action on vectors will be used in this work:

Given  $B_i \in \mathbb{C}^{k_2 \times k_i}$ ,  $i = 1, 2, 3$  with  $(k_1 + k_2 + k_3 = k)$  we have that

$$\exp(B) \equiv \exp \begin{pmatrix} & 0_{k_1, k} & \\ B_1 & B_2 & B_3 \\ & 0_{k_3, k} & \end{pmatrix} = I_{k, k} + \begin{pmatrix} & 0_{k_1, k} & \\ \varphi(B_2)B_1 & \varphi(B_2)B_2 & \varphi(B_2)B_3 \\ & 0_{k_3, k} & \end{pmatrix} \quad (9)$$

If  $k_2 \ll k$  then, since  $B_2 \in \mathbb{C}^{k_2 \times k_2}$ , is very simple and cheap to compute  $\varphi(B_2)$  and to evaluate  $\exp(B)$  or its action on a vector. Given  $v = (v_{k_1}, v_{k_2}, v_{k_3})^T \in \mathbb{C}^k$ ,  $B = (B_1, B_2, B_3) \in \mathbb{C}^{k_2 \times k}$  and denoting  $B \cdot v = B_1 v_{k_1} + B_2 v_{k_2} + B_3 v_{k_3} \in \mathbb{C}^{k_2}$ , we have that

$$\exp(B)v = (v_{k_1}, v_{k_2} + \varphi(B_2)(B \cdot v), v_{k_3}).$$

In addition, as we will see, for the schemes we obtain in this work the matrix  $B_2$  will have a small norm, typically  $B_2 = \mathcal{O}(h^s)$ , with  $s \geq 2$ , and then we can approximate the matrix  $\varphi(B_2)$ , for example, using only the first few terms of its Taylor expansion.

We also remark the following properties for some elements of the Lie algebra:

1. If  $\sigma = 0$ , then  $C_{\sigma=0}$  is a matrix with only one row with non zero elements ( $k_2 = 1$ )
2. The commutator

$$[C_{\sigma_1}, C_{\sigma_2}] = C_{\sigma_1} C_{\sigma_2} - C_{\sigma_2} C_{\sigma_1}$$

is a matrix with only two rows with non zero elements and it is also trivial to compute the exponential of this matrix ( $k_2 = 2$ ).

3. Each additional commutator introduces a new non empty row in the matrix.

We analyze how to obtain numerical methods at different orders by considering exponentials of elements of the Lie algebra such that the evaluation of the exponential for these elements can be cheaply and efficiently computed. Apart from the order conditions, there are additional constraints to be considered, for example, sixth-order methods without commutators necessarily involve the exponential of a companion matrix,  $e^{C\sigma}$ , with a negative  $\sigma$ .

Allowing exponentials of elements of the Lie algebra with a low computational cost which includes certain commutators, we derive sixth-order methods with positive  $\sigma$ .

## 1.1 Numerical integration by standard methods: Runge–Kutta methods

We consider Runge–Kutta (RK) methods as a representative of standard numerical integrators. The general class of  $s$ -stage (explicit or implicit) Runge–Kutta methods are characterized by the real numbers  $a_{ij}$ ,  $b_i$  ( $i, j = 1, \dots, s$ ) and  $c_i = \sum_{j=1}^s a_{ij}$ . For this linear problem they take the form

$$\begin{aligned} Z_i &= z_n + h \sum_{j=1}^s a_{ij} M_j Z_j, & i = 1, \dots, s \\ z_{n+1} &= z_n + h \sum_{i=1}^s b_i M_i Z_i, \end{aligned} \quad (10)$$

where  $M_i = M(t_n + c_i h)$ . If  $a_{ij} = 0$ ,  $j \geq i$  then the method is explicit and one can compute (and store) the vectors  $Z_1, \dots, Z_s$  sequentially. Otherwise, the method is implicit and one has to solve the linear system of equations

$$\begin{pmatrix} I - ha_{11}M_1 & -ha_{12}M_2 & \cdots & -ha_{1s}M_s \\ -ha_{21}M_1 & I - ha_{22}M_2 & \cdots & -ha_{2s}M_s \\ \vdots & \vdots & & \vdots \\ -ha_{s1}M_1 & -ha_{s2}M_2 & \cdots & I - ha_{ss}M_s \end{pmatrix} \begin{pmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_s \end{pmatrix} = \begin{pmatrix} z_n \\ z_n \\ \vdots \\ z_n \end{pmatrix}.$$

Explicit RK methods require only  $s$  products  $MZ$  and they need to store  $s$  vectors ( $M_i Z_i$ ,  $i = 1, \dots, s$ ). In this sense, RK methods can be considered as very cheap methods. However, in general, they require  $s$  evaluations of the functions  $f_i(t)$  (some methods require less number of evaluations and this depends on the nodes,  $c_i$ , of the method) and, since they can be considered as polynomial approximations to the solution, a poor performance is expected for stiff and oscillatory problems.

On the other hand, implicit RK methods can reach order  $2s$  and are suitable for stiff problems, but they require to compute the inverse of a matrix of dimension  $(sN) \times (sN)$  whose computational cost, in general, is  $s^3$  times more expensive than the inverse of a matrix of dimension  $N \times N$  (e.g. for sixth-order methods with  $s = 3$  we have that the inverse of this matrix is about  $s^3 = 27$  times more expensive than the inverse of a matrix of dimension  $N \times N$ ).

Exponential methods like Magnus integrators or commutator-free methods usually show a high accuracy and in this work, we propose new composition

of exponentials with similar accuracy at lower computational cost. The order conditions for the new composition methods are obtained by equating with the formal solution given by the Magnus series expansion in a similar way as the Taylor method is used to obtain the order conditions for RK method after expanding all terms. For this reason, we briefly review some results for Magnus integrators.

## 2 Magnus based integrators

Given the homogeneous linear equation (3), with formal solution,  $z(t) = \Phi(t)z(0)$ , the Magnus expansion expresses the fundamental matrix solution in terms of a single exponential as [18]

$$\Phi(t) = \exp(\Omega(t)), \quad \Omega(t) = \sum_{k=1}^{\infty} \Omega_k(t)$$

whose terms,  $\Omega_k(t)$ , are linear combinations of integrals and nested commutators involving the matrix  $M$  at different times. Thus, the first terms read

$$\Omega_1(t) = \int_0^t M(t_1)dt_1, \quad \Omega_2(t) = \frac{1}{2} \int_0^t dt_1 \int_0^{t_1} dt_2 [M(t_1), M(t_2)], \dots \quad (11)$$

The algebraic problem to numerically approximate  $\Omega$  considerably simplifies if we use the graded free Lie algebra generated by  $\{\alpha_1, \dots, \alpha_s\}$  where

$$\alpha_{i+1} = \frac{h^{i+1}}{i!} \left. \frac{d^i M(t)}{dt^i} \right|_{t=h/2} \quad (12)$$

$i = 0, 1, \dots, s-1$ . Here  $\alpha_i = \mathcal{O}(h^i)$  and then it can be considered as an element with grade  $i = 1, 2, \dots, s$  respectively. Using this grading, the algebraic structure of the Magnus expansion up to a given order in the time step simplifies considerably [15].

However, from the computational point of view, it is more convenient to replace the elements  $\alpha_i$  (derivatives) by linear a combination of the matrix  $M(t)$  evaluated at the nodes of a given quadrature rule (integrals). For example, it is possible to build methods of order  $2s$  with only  $s$  symmetric collocation points [14].

In particular, up to second-order, we have<sup>3</sup>  $\Omega^{[2]} = \alpha_1$ , up to fourth-order, we have

$$\Omega^{[4]} = \alpha_1 - \frac{1}{12}[\alpha_1, \alpha_2], \quad (13)$$

and up to sixth-order

$$\Omega^{[6]} = \alpha_1 + \frac{1}{12}\alpha_3 - \frac{1}{12}[12] + \frac{1}{240}[23] + \frac{1}{360}[113] - \frac{1}{240}[212] + \frac{1}{720}[1112] \quad (14)$$

---

<sup>3</sup>We denote by  $\Omega^{[p]}$  an approximation (no unique) to the solution  $\Omega$  up to order  $h^p$ , i.e.  $\Omega^{[p]} = \Omega + \mathcal{O}(h^{p+1})$ .

where  $[ij \dots kl]$  represents the nested commutator  $[\alpha_i, [\alpha_j, [\dots, [\alpha_k, \alpha_l] \dots]]$ . In order to obtain methods which can be easily used with any quadrature rule we introduce the averaged (or generalized momentum) matrices for the interval  $[t_n, t_{n+1}]$

$$A^{(i)}(h) \equiv \frac{1}{h^i} \int_{t_n}^{t_n+h} (t - t_{1/2})^i A(t) dt = \frac{1}{h^i} \int_{-h/2}^{h/2} t^i A(t + t_{1/2}) dt, \quad (15)$$

for  $i = 0, \dots, s-1$  where  $t_{1/2} = t_n + h/2$ .

To second order, we can take  $\alpha_1 = A^{(0)}$  (neglecting higher order terms), to order four, we can set (see [7] and references therein)

$$\alpha_1 = A^{(0)}, \quad \alpha_2 = 12A^{(1)} \quad (16)$$

and to order six

$$\alpha_1 = \frac{9}{4}A^{(0)} - 15A^{(2)}, \quad \alpha_2 = 12A^{(1)}, \quad \alpha_3 = -15A^{(0)} + 180A^{(2)}. \quad (17)$$

If  $b_i, c_i, i = 1, \dots, k$  denote the weights and nodes of a given quadrature rule of order  $p \geq 2s$ , then the momentum matrices can be computed as

$$A^{(i)} = h \sum_{j=1}^k b_j \left( c_j - \frac{1}{2} \right)^i A_j, \quad i = 0, \dots, s-1, \quad (18)$$

with  $A_j \equiv A(t_n + c_j h)$ , and the corresponding numerical methods will remain of order  $2s$ .

Notice that, while  $\Omega^{[2]}$  has the same sparsity as  $A$ , this is not the case for  $\Omega^{[p]}$  with  $p > 2$ , and then the computational cost of the exponential (or its action on a vector) can grow considerably.

To circumvent this problem we can consider, for example, commutator-free methods which we briefly present.

## 2.1 Commutator-free Magnus integrators

Commutator-free (CF) methods can be a simple and efficient alternative to solve the non-autonomous problem (3). These methods can be written, for one time step  $h$ , as the composition

$$z_{n+1} = \exp(hC_{\sigma_m}) \cdots \exp(hC_{\sigma_2}) \exp(hC_{\sigma_1}) z_n \quad (19)$$

where each  $C_{\sigma_k}$  has the structure given in (8) and must satisfy the consistency condition  $\sum_{k=1}^m \sigma_k = 1$ . Obviously, the coefficients involved on each exponent as well as the value of  $m$  depend on the method.

**Second order methods.** Second order methods can be obtained with the very simple scheme

$$z_{n+1} = \exp(\alpha_1) z_n = \exp(M^{(0)}) z_n \quad (20)$$

which can also be considered as a second order Magnus or Fer integrator, and where we can approximate  $M^{(0)}$ , e.g., using the midpoint or the trapezoidal rule, i.e.,

$$M^{(0)} = hM(t_n + h/2) \quad \text{or} \quad M^{(0)} = \frac{h}{2}(M(t_n) + M(t_n + h)).$$

**Fourth order methods.** Fourth order methods can be obtained for  $m \geq 2$ . A simple two-stage method ( $m = 2$ ) is given by [10] (using the relation (16))

$$\begin{aligned} z_{n+1} &= \exp\left(\frac{1}{2}\alpha_1 + \frac{1}{6}\alpha_2\right) \exp\left(\frac{1}{2}\alpha_1 - \frac{1}{6}\alpha_2\right) z_n \\ &= \exp\left(\frac{1}{2}M^{(0)} + 2M^{(1)}\right) \exp\left(\frac{1}{2}M^{(0)} - 2M^{(1)}\right) z_n \end{aligned} \quad (21)$$

where we can take, for example

$$\begin{aligned} M^{(0)} &= \begin{cases} \frac{h}{6}\left(M(t) + 4M(t + h/2) + M(t + h)\right) & \text{Simpson rule} \\ \frac{h}{2}\left(M(t + c_1h) + M(t + c_2h)\right) & \text{Gaussian quadrature rule} \end{cases} \\ M^{(1)} &= \begin{cases} \frac{h}{12}\left(M(t + h) - M(t)\right) & \text{Simpson rule} \\ \frac{\sqrt{3}h}{12}\left(M(t + c_2h) - M(t + c_1h)\right) & \text{Gaussian quadrature rule} \end{cases} \end{aligned}$$

where  $c_1 = \frac{1}{2} - \frac{\sqrt{3}}{6}$ ,  $c_2 = \frac{1}{2} + \frac{\sqrt{3}}{6}$ .

With three exponentials, a standard method is

$$\begin{aligned} z_{n+1} &= \exp\left(\frac{1}{12}\alpha_2\right) \exp(\alpha_1) \exp\left(-\frac{1}{12}\alpha_2\right) z_n \\ &= \exp\left(M^{(1)}\right) \exp\left(M^{(0)}\right) \exp\left(-M^{(1)}\right) z_n. \end{aligned} \quad (22)$$

In general, the 2-exponential method provides slightly more accurate results. However, for the problem of interest (3)-(4), it is obvious from (12) that  $\alpha_1 = hM(h/2)$  which has the structure of a companion matrix like (8), while the matrices associated to  $\alpha_i$ ,  $i > 1$  have only one non-zero row, i.e., they have the form

$$\alpha_2 = h^2 \begin{pmatrix} 0_{(N-1) \times (N+1)} \\ F_{1 \times (N+1)} \\ 0_{1 \times (N+1)} \end{pmatrix},$$

where  $0_{m \times n}$  denotes a zero matrix of dimension  $m \times n$  and  $F_{(1 \times N+1)} = (F_1, \dots, F_{N+1})$  denotes a row vector. Notice that for this particular problem,  $\exp(M^{(1)})$  and  $\exp(-M^{(1)})$  can be written in a very simple closed form and the three-exponential method (22) is, in general, faster to be computed than the scheme with only two exponentials (21), and can provide a better performance.

**Example 1:** Let us consider the following fourth-order non-homogeneous linear equation

$$x^{(iv)} + f_2(t)x'' + f_0(t)x = g(t)$$

with

$$f_0(t) = 100 \left( 1 + \frac{1}{4} \cos(t) \right), \quad f_2(t) = 50 \left( 1 + \frac{1}{4} \sin(t) \right), \quad g = \operatorname{erf}(t).$$

Notice that

$$(M^{(1)})^2 = 0 \quad \Rightarrow \quad \exp(M^{(1)}) = I + M^{(1)}$$

and then the 3-exponential method, for this problem, is given by

$$(I + M^{(1)}) \exp \begin{pmatrix} 0 & h & 0 & 0 & 0 \\ 0 & 0 & h & 0 & 0 \\ 0 & 0 & 0 & h & 0 \\ -f_0^{(0)} & 0 & -f_2^{(0)} & 0 & g^{(0)} \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} (I - M^{(1)}) \quad (23)$$

being an algorithm with less complexity than the 2-exponential method because it only requires exponentiation of one companion matrix.

In Figure 1 we show the 2-norm error of the fundamental matrix solution at  $T = 10$  versus the number of time dependent function evaluations of the extended matrix  $M(t)$ . We compare with the explicit standard 4-stage fourth-order RK method (RK4) where  $M(t)$  is evaluated at the same nodes as the Simpson rule, and the implicit 2-stage fourth-order RK method where  $M(t)$  is evaluated at Gaussian nodes (GaussL4). For the exponential methods we also consider the Gaussian quadrature rule.

This problem has oscillatory solutions and the exponential methods are much more accurate at the same number of time-dependent function evaluations. However, the cost of a method also depends on its complexity. In addition to the evaluation of the time-dependent functions, the explicit RK method requires a few number of products (and to store 4 vectors), the implicit RK method has to invert a matrix of twice the dimension of  $M(t)$ , and it is considerably more costly than the explicit method. The fourth-order exponential integrators (Magnus integrator (Mag4), the 2-exponential CF method (CF42) and the 3-exponential CF method (CF43)) require to approximate the exponentials up to a given order of accuracy [1]. The method CF42 is the most accurate but CF43, which is only slightly less accurate, is cheaper to compute.  $\square$ .

In general, sixth-order CF methods use compositions with  $m \geq 5$  exponentials [2, 10] and in each of them it appears  $\alpha_1$ , which is the element which makes the computation of the exponential to be relatively involved. In addition, at least in one of the exponentials  $\alpha_1$  appears multiplied by a negative coefficient. These results motivated us to extend the analysis to order six.

We analyze new composition methods which allows us to obtain sixth-order methods with positive coefficients while being cheaper to compute than the existing CF methods.

Figure 1: Error in norm of the fundamental matrix solution,  $\|\Phi(T, 0) - \Phi_{ap}(T, 0)\|$ , where  $\Phi_{ap}$  denotes the numerical solution for a given method, versus the number of time-dependent function evaluations for the problem in Example 1.

### 3 New hybrid composition methods

In addition to the simplified structure of the matrix associated to  $\alpha_2$  we observe that in the system (3)-(4) the following elements of the Lie algebra show a very similar structure

$$\alpha_3 = h^3 \begin{pmatrix} 0_{(N-1) \times (N+1)} \\ G_{1 \times (N+1)} \\ 0_{1 \times (N+1)} \end{pmatrix}, \quad [\alpha_j, \alpha_k] = h^{j+k} \begin{pmatrix} 0_{(N-2) \times (N+1)} \\ K_{2 \times (N+1)} \\ 0_{1 \times (N+1)} \end{pmatrix},$$

i.e., they only contain one and two non-empty rows and their norms are proportional to  $\mathcal{O}(h^3)$  and  $\mathcal{O}(h^{j+k})$ , respectively.

The goal is to build composition methods with as few exponentials involving the element  $\alpha_1$  as possible to reach a given accuracy and leaving the remaining exponentials with cheaply computable matrices.

In addition, in this work we only consider time-symmetric methods, i.e., a map  $S(h)$  such that  $S^{-1}(h) = S(-h)$ . This approach simplifies the construction of methods and the methods share this property with the exact solution. In general, the most efficient composition methods in the literature have this symmetry. In order to consider a symmetric composition we proceed as follows, given  $C_1(h), C_2(h)$  odd and even functions of  $h$ , i.e.,  $C_1(-h) = -C_1(h)$ ,  $C_2(-h) = C_2(h)$ , then if  $S_k(h)$  is a symmetric composition the following composition

$$S_{k+1}(h) = e^{C_1(h)+C_2(h)} S_k(h) e^{C_1(h)-C_2(h)}$$

is also time-symmetric.

We denote the scheme by the number of exponentials involving  $\alpha_1$  and the following sixth-order methods are studied.

**One-exponential method** Let us start with the fourth-order method (22) and suppose we use a sixth-order quadrature rule so,  $\alpha_3$  can be added to the symmetric composition and it can be used for optimization purposes, i.e.,

$$\Phi_3^{[4]} = \exp\left(\frac{1}{12}\alpha_2 + z_2\alpha_3\right) \exp(\alpha_1 + z_1\alpha_3) \exp\left(-\frac{1}{12}\alpha_2 + z_2\alpha_3\right). \quad (24)$$

This schemes has two parameters,  $z_1, z_2$ , to be chosen. Using the Baker-Campbell-Hausdorff (BCH) formula and equating to (14) we find that, by consistency,  $z_1 + 2z_2 = 1/12$ , and this leaves us with a free parameter which can be used to reduce the error. Since  $z_1, z_2$  multiply  $\alpha_3$ , they will appear linearly on the leading error terms at order 5 in [23] and [113]. If we consider that the commutator [113] (which contains two operators  $\alpha_1$ ) is more relevant for the error of the method, we can use the free parameter to cancel this term.

On the other hand, since a commutator contains only two non-empty rows, we could add to the first and last exponential a linear combination of the commutators [12], [13] and [23]. Since [12], [23] are odd operators in  $h$  we will include them symmetrically distributed while [13] being an even operator in  $h$  will be distributed skew-symmetrically. In this way, we obtain the following symmetric composition scheme which contains six free parameters to solve the order conditions

$$\begin{aligned} \Phi_1^{[6]} &= e^{z_2\alpha_2+z_3\alpha_3+[\alpha_1+z_4\alpha_2,z_5\alpha_1+z_6\alpha_3]} \\ &e^{\alpha_1+z_1\alpha_3} \\ &e^{-z_2\alpha_2+z_3\alpha_3+[-\alpha_1+z_4\alpha_2,z_5\alpha_1+z_6\alpha_3]}. \end{aligned} \quad (25)$$

Apparently, there is the same number of order conditions as parameters, however, we found that there is a free parameter which we can use to reduce some of the error terms at leading order. In a similar way to the optimization process mentioned for the fourth-order method, we choose this parameter to cancel the coefficient which multiplies [11113]. The solution obtained is:

$$z_1 = \frac{1}{28}, \quad z_2 = \frac{1}{10}, \quad z_3 = \frac{1}{42}, \quad z_4 = -\frac{3}{4}, \quad z_5 = \frac{1}{90}, \quad z_6 = \frac{1}{840}.$$

The next question is: can we obtain an eight-order method adding new terms of similar complexity to the previous scheme?

If we use an eight-order quadrature rule, we have to take into account  $\alpha_4$  in the scheme, but now we have to consider that

$$\begin{aligned} \Omega^{[8]} &= \Omega^{[6]} - \frac{1}{80}[14] \\ &+ \mathcal{L}\left([34], [124], [223], [313], [412], [1114], [1123], [1312], [2113], [2212], \right. \\ &\quad \left. [11113], [11212], [21112], [111112]\right), \end{aligned}$$

where  $\Omega^{[6]}$  is given in (14) and  $\mathcal{L}$  denotes a linear combination of the elements which are of order  $\mathcal{O}(h^7)$ . The composition we can build is:

$$\begin{aligned} \tilde{\Phi}_1^{[6]} &= e^{z_2\alpha_2+z_3\alpha_3+[\alpha_1+z_4\alpha_2,z_5\alpha_1+z_6\alpha_3]+a_1\alpha_4+a_2[14]+a_3[24]+a_4[34]} \\ &e^{\alpha_1+z_1\alpha_3} \\ &e^{-z_2\alpha_2+z_3\alpha_3+[-\alpha_1+z_4\alpha_2,z_5\alpha_1+z_6\alpha_3]-a_1\alpha_4+a_2[14]-a_3[24]+a_4[34]}. \end{aligned} \quad (26)$$

We have four new parameters,  $a_1, a_2, a_3, a_4$  multiplying terms with  $\alpha_4$  which must satisfy  $a_1 + 2z_5 a_3 = 1/80$  in order to match the condition for [14] which is necessary for the method to be of order six. The three remaining parameters are used to reduce the error from the terms [34], [124], [412], [1114]. To reach order eight, 11 parameters are needed, but only 10 independent terms are available including all combinations with double commutators, and this has not been explored.

If an eight-order quadrature rule is used, the following relations must be used [8]

$$\begin{aligned}\alpha_1 &= \frac{9}{4}A^{(0)} - 15A^{(2)}, & \alpha_2 &= 15(5A^{(1)} - 28A^{(3)}), \\ \alpha_3 &= -15A^{(0)} + 180A^{(2)}, & \alpha_4 &= -140(3A^{(1)} - 20A^{(3)}).\end{aligned}$$

**Two-exponential method** We next explore the following scheme with seven parameters to solve six order conditions leaving a free parameter:

$$\begin{aligned}\Phi_2^{[6]} &= e^{z_3\alpha_2+z_4\alpha_3+[\alpha_1+z_5\alpha_2,z_6\alpha_1+z_7\alpha_3]}e^{\alpha_1/2+z_1\alpha_2+z_2\alpha_3} \\ &e^{\alpha_1/2-z_1\alpha_2+z_2\alpha_3}e^{-z_3\alpha_2+z_4\alpha_3+[-\alpha_1+z_5\alpha_2,z_6\alpha_1+z_7\alpha_3]}.\end{aligned}\quad (27)$$

There is a free parameter that, as in the previous case, is used to cancel the coefficient at order seven which multiplies [11113]. The solution obtained is:

$$z_1 = \frac{1}{10}, \quad z_2 = \frac{89}{4536}, \quad z_3 = \frac{3}{80}, \quad z_4 = \frac{25}{1134}, \quad z_5 = -\frac{51}{976}, \quad z_6 = \frac{61}{1530}, \quad z_7 = \frac{61}{68040}.$$

**Three-exponential method** We propose a new CF methods, and this implies to allow one of the coefficients multiplying  $\alpha_1$  to be negative. The following CF method is considered

$$\Phi_3^{[6]} = e^{z_6\alpha_2+z_7\alpha_3}e^{z_3\alpha_1+z_4\alpha_2+z_5\alpha_3}e^{z_1\alpha_1+z_2\alpha_3}e^{z_3\alpha_1-z_4\alpha_2+z_5\alpha_3}e^{-z_6\alpha_2+z_7\alpha_3}.$$

Two real solutions are obtained, one with  $z_1 < 0$  and one with  $z_3 < 0$ . The solution with  $z_1 < 0$  is:

$$\begin{aligned}z_1 &= -0.134081437730954855148833, & z_2 &= -0.012669129450624949118909, \\ z_3 &= 0.567040718865477427574417, & z_4 &= 0.156797955467217572935920, \\ z_5 &= 0.032555028141095211662211, & z_6 &= 0.015446203250883929563910, \\ z_7 &= 0.015446203250883929563910.\end{aligned}\quad (28)$$

At least three exponentials including  $\alpha_1$  are necessary in order to solve the order conditions associated to the elements of the algebra  $\alpha_1$ , [12] and [1112]. That was not possible with the one- and two-exponential methods.

## 4 Numerical Examples

In this section we analyse the performance of the following methods:

Figure 2: Same as Fig. 1 for the sixth-order methods. Here  $H63$  and  $H64$  denote the new sixth-order hybrid methods with three and four exponentials given by (25) and (27), respectively.

- The 7-stage sixth-order explicit RK method (RK6) with coefficients given in [12, page 177] which requires 5 new evaluations of the matrix  $M(t)$  per step.
- The 3-stage sixth-order implicit Runge-Kutta-Gauss-Legendre method (GaussL6) which requires 3 new evaluations of the matrix  $M(t)$  per step.
- The one-exponential sixth-order Magnus integrator (Mag6) using the Gauss quadrature rule [8].
- The 6-exponential sixth-order CF method from [2].
- The 1-exponential sixth-order Hybrid method (H61) given in (25).
- The 2-exponential sixth-order Hybrid method (H62) given in (27).
- The 3-exponential sixth-order Hybrid method (H63) given in (28).

As a first test, we repeat the numerical integration in Example 1. The results are shown in Figure 2. We observe that all exponential methods are clearly superior to the explicit and implicit RK methods. The CF6 method is the most accurate, but the hybrid methods are cheaper to compute. Obviously, the relative computational cost between them will depend on each particular problem, but the the cost of H61 and H62 could be up to twice cheaper the cost of the method CF6. In addition, these two methods have positive coefficients multiplying  $\alpha_1$  and this could be of interest for some problems.

As we have mentioned, the solution of this equation is oscillatory. When the coefficients of the equation oscillate with a frequency close to the frequency of the system, a parametric resonance can appear. This is the case, e.g. for the well known Mathieu equation  $x'' + (w^2 + \epsilon \cos(t))x = 0$  for  $w$  close the resonant values  $w = 0, 1, 2, \dots$

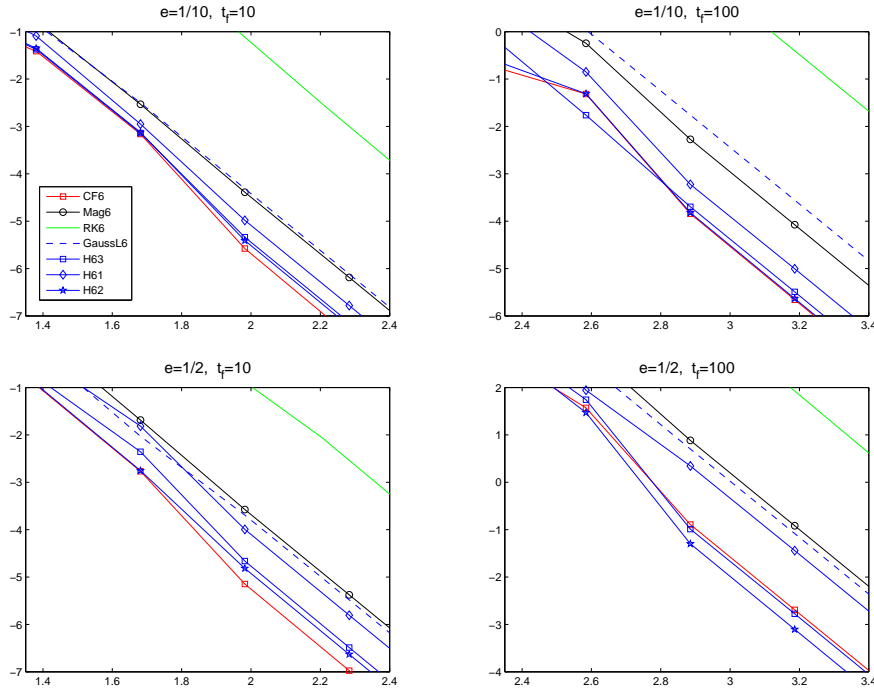

Figure 3: The two-norm error in the fundamental matrix solution for the sixth-order methods applied to the problem (29)-(30) computed at the final times  $t_f = 10$  (left figures) and  $t_f = 100$  (right figures) for the choices  $e = 1/10$  (top figures) and  $e = 1/2$  (bottom figures).

**Example 2:** Let us now consider the same fourth-order non-homogeneous linear equation

$$x^{(iv)} + f_2(t)x'' + f_0(t)x = g(t) \quad (29)$$

but with

$$f_0(t) = 5(1 + e \cos(\omega t)), \quad f_2(t) = 4(1 + e \sin(\omega t)), \quad (30)$$

that has parametric resonances for values of  $\omega$  around  $\omega = 1$  and  $\omega = 2$ . We take  $\omega = 2$  and integrate the fundamental matrix solution until the final time  $t_f = 10$  and we repeat it until  $t_f = 100$ . The solution is very sensitive to the parameter  $e$  and we repeat the computations for  $e = 1/10$  and  $e = 1/2$ . Figure 3 shows the results obtained.

We observe that the error grows with the final time as well as with the choice of the parameter  $e$ , and the new hybrid methods show an excellent performance since they are among the most accurate as well as the cheapest to compute (despite the explicit RK method which show a very poor performance). Similar results are obtained for the numerical integration of the Mathieu equation for values of the parameters on the instability region. If one is interested to find the stability regions for a given set of parameters of the equation, usually this is done with the numerical integration of the equations repeatedly for many different choices of the parameters, and efficient methods need to be fast and

accurate, being the methods presented in this work of great interest for these problems.

## 5 Conclusions

We have studied the numerical integration of high-order linear non-homogeneous differential equations written as first order homogeneous linear equations (which show a particular algebraic structure in terms of the companion matrix) using exponential methods. We have shown how to build new methods which can be considered as hybrid methods between Magnus and commutator-free methods. The new methods can reach similar accuracy as previous exponential methods, but with a reduced complexity. Additional parameters can be included into the scheme for optimization purposes. We have shown how to obtain the order conditions to build sixth-order methods and several methods are obtained. The performance of the new methods has been tested on several numerical problems.

As a further application of the results of the present work, we remark that homogeneous non-autonomous linear differential equations describe the evolution of many dynamical systems in classical and quantum mechanics (see [6, 7] and references therein) as well as in biology [23] or engineering [3, 5, 11]. It is straightforward to extend the here presented analysis to the class of homogeneous non-autonomous equations

$$x' = M(t)x, \quad (31)$$

where  $M(t) = A + B(t)$  such that the evaluation of  $\exp(M(t))$  is computationally demanding but  $\exp(B(t))$  can be trivially computed. One can either use the methods derived in this work or build new exponential methods for particular problems. This requires the analysis of the Lie algebra associated to the Matrix  $M(t)$ . If the analysis carried out on a family of problems indicate that some other elements of the Lie algebra can also be efficiently computed, these elements can also be considered in the scheme in a similar way as shown in this work.

On the other hand, it is well known that the computational cost of a given method strongly depend on the problem to be solved. As we have mentioned, an  $s$ -stage fully implicit RK method requires to compute the inverse of a large matrix which is about  $s^3$  times the cost of the inverse of a  $N \times N$  matrix, and the inverse of a matrix can be carried out at the cost of  $4/3$  the product of two matrices [1]. Then, for a sixth-order method with  $s = 3$  the total cost is 3 evaluations of the  $M(t)$  and  $s^3 \frac{4}{3} = 36$  products. On the other hand, one can approximate  $e^{hM}$  using a Padé approximation up to accuracy of order  $\mathcal{O}(h^{10})$  with 3 products and one inverse, i.e. at the cost of only  $(4 + 1/3)$  products (or using the Paterson-Stockmeyer scheme to compute the Taylor expansion up to  $\mathcal{O}(h^9)$  with only 4 products [1]). Obviously, the cost of each matrix-matrix multiplication will depend on the sparsity of the matrix, and this is different for Magnus and commutator-free methods as well as for the new methods. This analysis has to be taken into account to consider the most efficient methods for a given class of problems or to build new methods following the procedure

studied in this work (where we can add extra parameters for optimization) being an interesting problem to be considered.
